Enabling the Unavailable Trip: Consumer Welfare and Willingness to Pay for Multimodal Technology

Michela Bonani and Julian Hidalgo

Universitat Pompeu Fabra and BSE

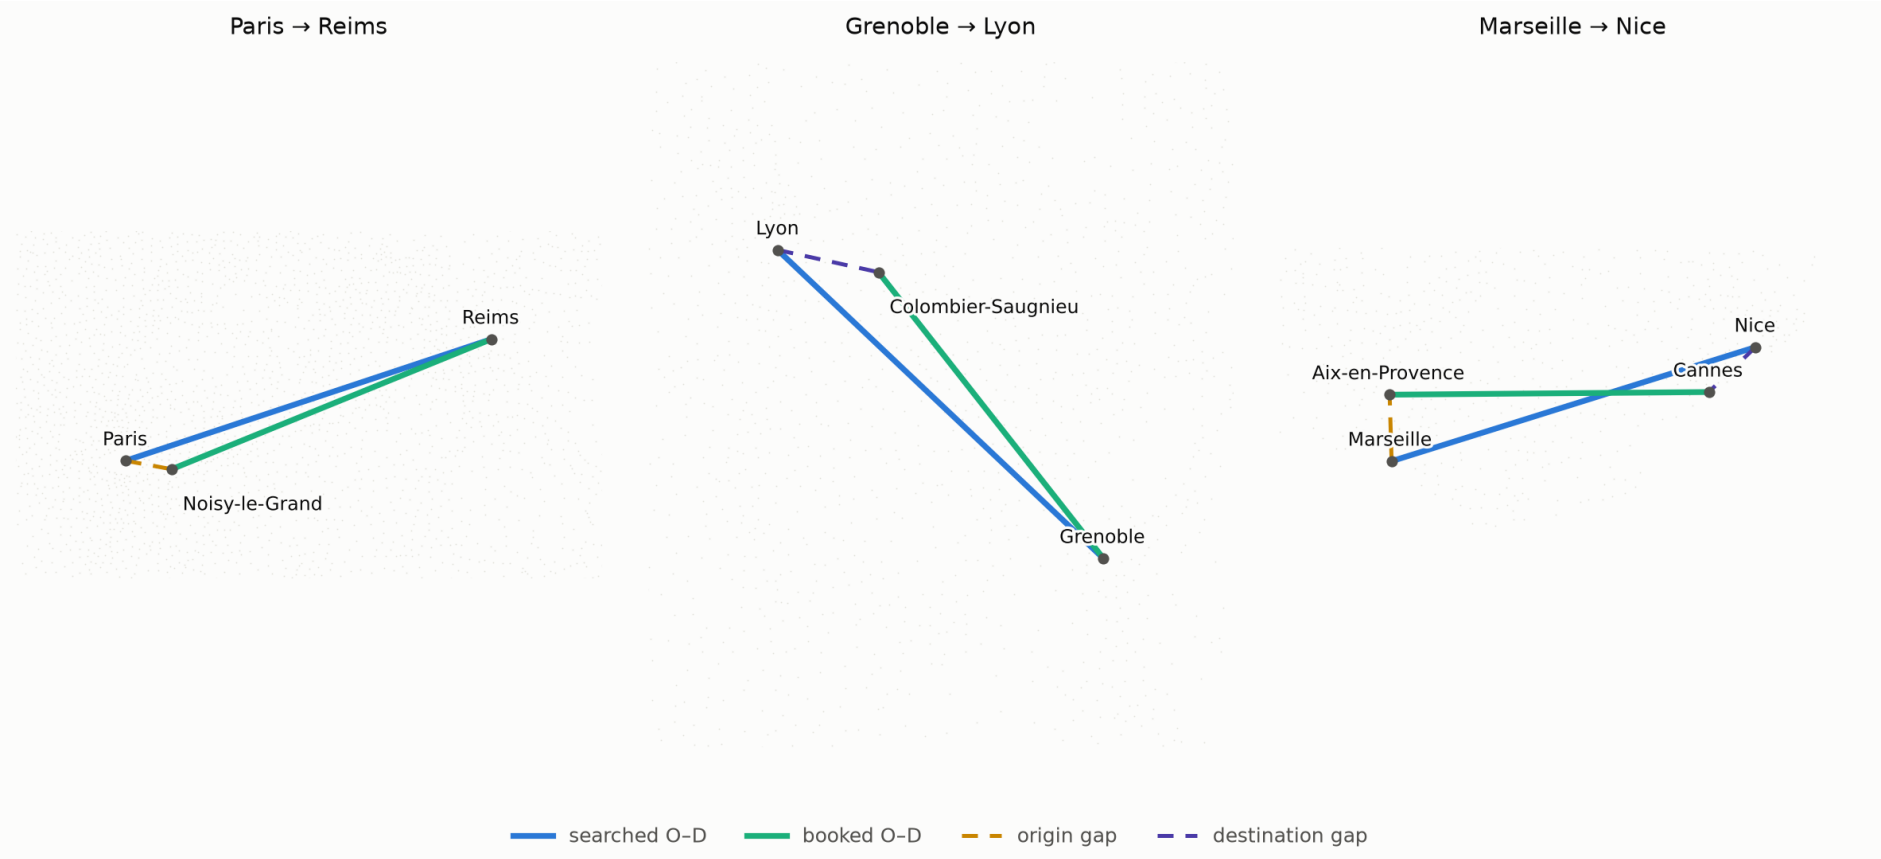

November 9, 2026

When the chosen option is not the optimal one

- In many markets, consumers cannot buy exactly the option they would most prefer.
- Frictions (search costs, limited availability, timing, coverage) push them toward a *near-match*: a substitute that differs from their ideal choice.
- The consumer then bears the cost of bridging that gap.

This paper: measure this mismatch, its cost to consumers, and the value of reducing it in **long-distance travel**.

An example: long-distance travel

Blue: the origin–destination the traveler searched. Green: the trip actually booked. Dashed: the spatial gap the traveler must cover themselves.

Motivation

- On a long-distance platform, **about one booking in three (34%)** is for an origin and/or destination different from the one searched.
- The EU is promoting an integrated, multimodal transport sector (European Commission 2017, 2023; European Parliament 2026).
- Digital platforms can facilitate integration by allowing travelers to **combine modes within a single trip**, making otherwise-unavailable itineraries feasible.
- Yet how much multimodal integration can improve consumer welfare remains an open empirical question.

Demand costs and supply frictions

On the demand side, a traveler who cannot book the searched trip faces search and coordination costs — and the cost of covering the spatial gap themselves.

On the supply side, two frictions generate these mismatches:

- **Coverage:** the searched origin–destination (OD) is not served.
- **Capacity / timing:** a trip exists, but none matches the searched OD when the traveler searches.

Multimodal integration can relax both : more OD pairs feasible (extensive margin) and more options on served routes (intensive margin).

This paper

We study **BlaBlaCar**, the largest long-distance carpooling platform, which also operates its own scheduled buses (*BlaBlaBus*) — two intercity modes on a single interface, in France.

Three questions:

- What frictions prevent travelers from realizing their preferred trips? [preliminary evidence]
- How much do these frictions affect travel choices and welfare? [structural demand model]
- To what extent can multimodal integration improve consumer outcomes? [counterfactuals]

Preview of results

- **Spatial mismatches are common — and not just missing supply.**
  Gaps average ≈50 km; most mismatches arise despite existing network coverage.

- **Mismatches are costly, and consumers would pay to remove them.**
  Disutility is driven by large origin/destination gaps — consumers are largely indifferent to minor ones; WTP ≈ EUR 14.1 per 100 km, EUR 6.95 for the average 49.3 km gap (about a third of a fare), and higher for older and privacy-sensitive travelers.

- **Closing the gap raises welfare, expands the market, and can be priced.**
  +EUR 0.57 per searcher (EUR 5.6 per booking; ≈EUR 10.4M, a quarter of a fare, no new capacity); booking rate rises 10.75%→11.6%, mostly carpool; break-even surcharge EUR 5.12, about 25% of the fare.

Our contribution: we identify and *quantify* the consumer cost of searched-vs-booked mismatches and the value of integrating modes.

Institutional background & data

BlaBlaCar platform

Data

Proprietary BlaBlaCar data — 100 most popular routes in France, Nov 2021–Nov 2022.

- **Searches** (one row per query): searched OD, date, displayed choice set and prices, clicks, and demographics (gender, age group).
- **Bookings** (carpool and bus files): booked OD, actual pick-up/drop-off, prices, seats, and trip distance and duration.
- **Supply**: bus inventory (services, capacity, stops) and cars offered per route–date; cars and buses at each location (endpoint connectivity).
- **Additional**: municipality coordinates (to measure spatial gaps) and daily fuel prices (price instruments).

≈18.3M searches, ≈1.16M bookings.

▸ Descriptive statistics

Preliminary evidence

Preliminary evidence: what we document

1. **Magnitude and heterogeneity** of origin–destination mismatches.
2. **Determinants of the frictions** — the nature of a mismatch, across modes and margins.
3. **Willingness to multimode** — do travelers accept, and value, alternative itineraries?

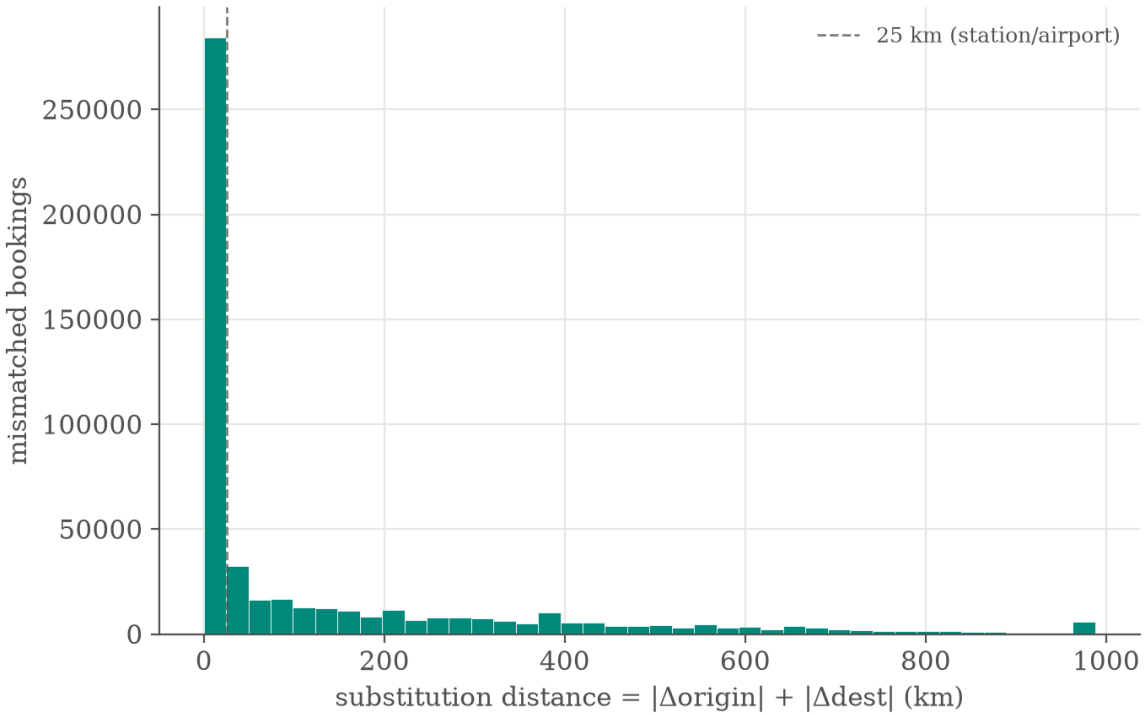

One booking in three is a near-match — and far more for carpool

	Total	Bus	Carpool
Number of bookings	1,163,897	629,626	534,271
Search–booking match (%)	66.0	82.2	46.9
Origin gap only (%)	15.1	5.8	26.1
Destination gap only (%)	16.1	11.9	21.0
Origin and destination gaps (%)	2.9	0.2	6.1
Trip distance (km)	210.0	223.0	200.0
Origin gap (km)	12.5	133.7	10.2
Destination gap (km)	10.7	5.8	13.0
Origin + destination gap (km)	46.2	23.2	46.9

Distance rows are medians. 34% of bookings are near-matches: 53% of carpool vs. 18% of bus.

▸ Mismatch maps

Most mismatches are small — but a long tail is large

CDF of the origin + destination gap; strongly right-skewed — about 55% of near-matches are within 25 km, the rest substantially larger.

▸ Mismatch maps

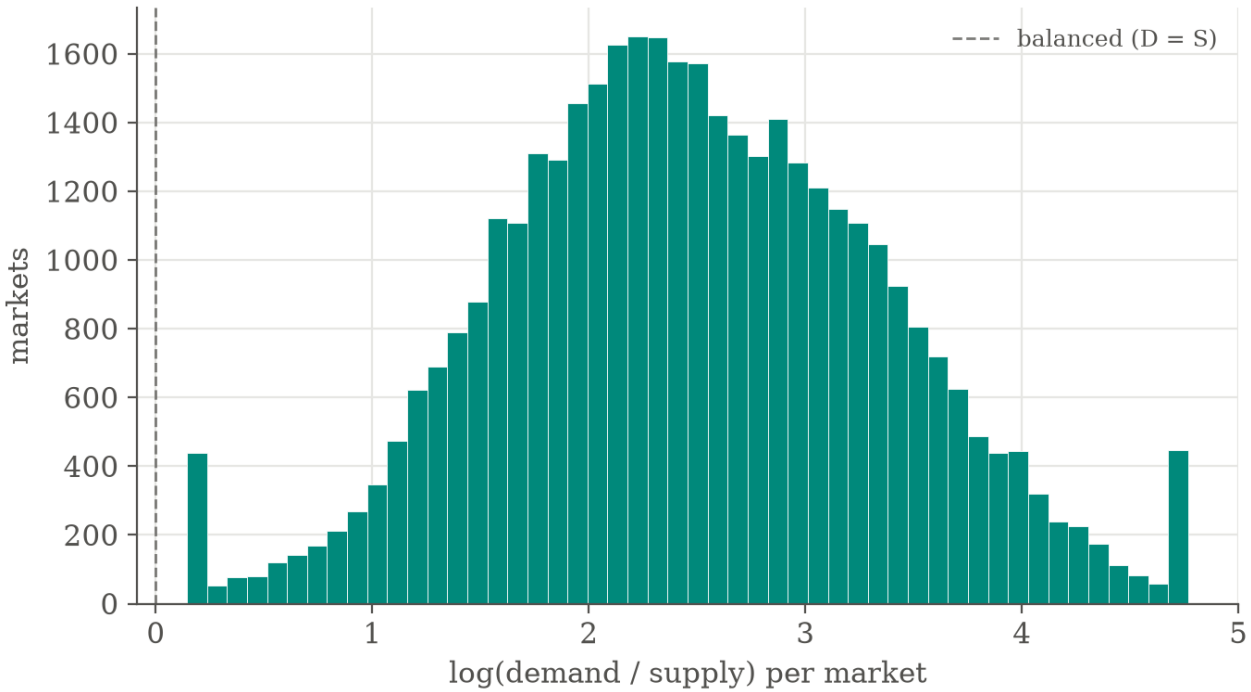

Options usually exist — the friction is matching, not coverage

	Underserved no supply	Congestion supply, no option	Other option existed
A. Near-match bookings (booked OD $\neq$ searched)			
Carpool	8.6	0.9	90.6
Bus	49.7	2.2	48.0
B. Searches without a booking			
Carpool	8.1	11.0	80.9
Bus	24.6	5.3	70.1

All values in %. Denominators: near-matched bookings (A; carpool 283,901, bus 111,913) and all searches (B; 20,621,323 per mode). Across both margins "option existed" dominates — buses aside, where missing coverage explains about half of near-matches and a quarter of unbooked searches.

▸ Displayed vs. offered

Displayed options fall short of demand in nearly every market

Distribution of $\log(\text{demand}/\text{supply})$ across markets (searches vs. displayed results); mass almost entirely above zero. What a traveler sees is the supply *at the time of search*, not total supply on the route.

Willingness to multimode: specification

$$P(Y = 1 \mid \cdot) = G\big(\beta_1\, Conn_{o,d} + \beta_2\, Conn_{o,d} \times Unserved_{o,d} + \beta_3 X'\big)$$

- $Conn_{o,d}$: cars + buses touching the searched origin and destination (leave-one-out).
- X': displayed price and displayed direct supply; SE clustered on origin.

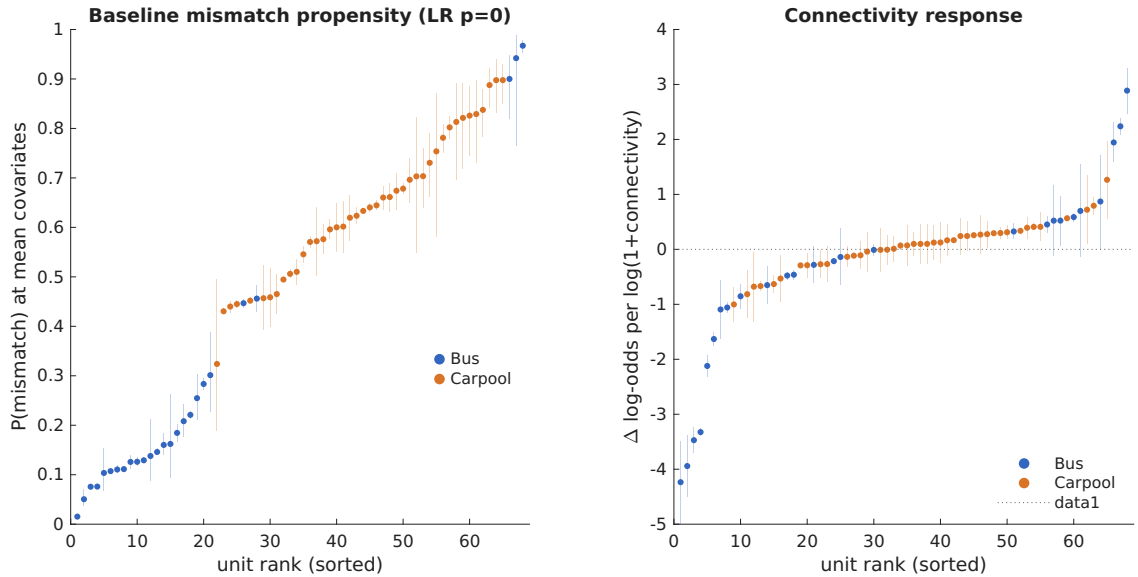

Three outcomes:

(A) **Conversion** — book, over all searches.

(B) **Any near-match** — booked OD $\neq$ searched, conditional on booking.

(C) **Severe near-match** — gap above the median.

Propensity to multimode varies widely — and rises with connectivity for carpool

Each point = origin×mode unit ($\geq$50 bookings). *Left*: baseline near-match probability (higher for carpool). *Right*: response to endpoint connectivity (mostly ≥ 0); common response rejected ($p \approx 0$). In the regressions, connectivity raises near-match bookings significantly for carpool, not for bus.

▸ Connectivity estimates

Structural model

Modeling choices

Why a structural model? To recover price sensitivity and the disutility of the gap, and to quantify the welfare value of integration

- **Static discrete choice**: consumers decide at the time of search, over the trips available then; we abstract from purchasing-horizon dynamics.
- **Each search is an independent choice** (no consumer panel).
- **Choice set**: trips aggregated to mode $\times$ 6-hour window $\Rightarrow$ 9 alternatives (8 inside + outside).
- **Outside option**: own car, train, other operators, or no trip.
- **Estimation sample**: most-booked routes, up to 24 dates each ($\approx$1,458 markets, 89 routes, 13 months, $\approx$169k bookings).

The spatial gap G_{jm}

$$G_{jm} = \underbrace{g^o_{jm}}_{\text{origin gap}} + \underbrace{g^d_{jm}}_{\text{destination gap}}, \qquad G_{jm} = 0 \text{ for an exact match} \tag{1}$$

- g^o_{jm}, g^d_{jm}: great-circle distance between the *searched* and *booked* origin (resp. destination), averaged over the bookings of trip j, per 100 km.
- Main measure: the sum $g^o + g^d$. Positive for a near-match; the displacement the traveler must cover themselves.
- Robustness: origin/destination gap shares, split into *minor* (0.5–25 km) and *severe* (>25 km).

Demand — individual utility

$$U_{ijm} = \underbrace{\delta_{jm}}_{\text{baseline utility}} + \underbrace{\pi^{p}\, d_i\, p_{jm} + \pi^{x}\, d_i\, x_{jm} + \varepsilon_{ijm}}_{\text{deviation from baseline}} \tag{2}$$

- i indexes the consumer; d_i are demographics (age, gender).
- p_{jm} price; x_{jm} trip characteristics (bus vs. carpool, route distance, departure window).
- π^{p}, π^{x}: how price sensitivity and mode preferences vary across demographics.
- $\varepsilon_{ijm} \sim MVN(0, \Omega)$: unobserved taste, correlated across trips (factor structure).
- Outside option normalized: $U_{i0m} = \varepsilon_{i0m}$ (own car, train, other operators, no trip).

Demand — baseline utility δ_{jm}

$$\delta_{jm} \;=\; \alpha\, p_{jm} \;+\; \beta\, x_{jm} \;+\; \gamma\, G_{jm} \;+\; \xi_{jm} \tag{3}$$

- α: common price sensitivity; β: common taste for trip characteristics.
- γ: disutility of the searched↔booked gap — *the object of interest*.
- ξ_{jm}: unobserved trip quality (amenities, driver attributes) — source of price endogeneity.

Estimation and identification

Two-stage, individual-level estimation (Goolsbee–Petrin, 2004) — a micro-BLP using consumer choices directly.

First stage (micro):

- SML with trip–market FE δ_{jm}; recovers heterogeneity π^p, π^x and covariance $\sigma_P, \sigma_C, \sigma_W$.

Second stage (market):

- Project δ_{jm} on price, characteristics, gap (2SLS) $\Rightarrow \alpha, \beta, \gamma$.

- **Flexible substitution** via a factor structure on tastes:

$$\varepsilon_{ijm} = \sigma_P \, \nu_i^P + \sigma_C \, \nu_{i,c(j)}^C + \sigma_W \, \nu_{i,w(j)}^W + \eta_{ijm}$$

Identification:

- **Variation in the searched↔booked gap** across displayed trips identifies γ
  a near-match in m is an exact-match posted for another market m'; the algorithm, not the driver, displays it in m
- **Cost-per-seat shifters** (fuel $\times$ distance, tolls, labor) identify price sensitivity α
- **Demographic variation in bookings** identifies the heterogeneity π^p, π^x

▸ Full estimates

Willingness to pay

WTP in EUR per 100 km of gap. Average 14.1 EUR/100 km; 6.95 EUR for the average 49.3 km gap (≈ a third of a fare). Age 10–29 pay below 11 EUR; older groups 56–63% more; privacy-sensitive (unreported) 18.4 EUR. Point estimates with 5–95% parametric-bootstrap range.

▸ How WTP is computed

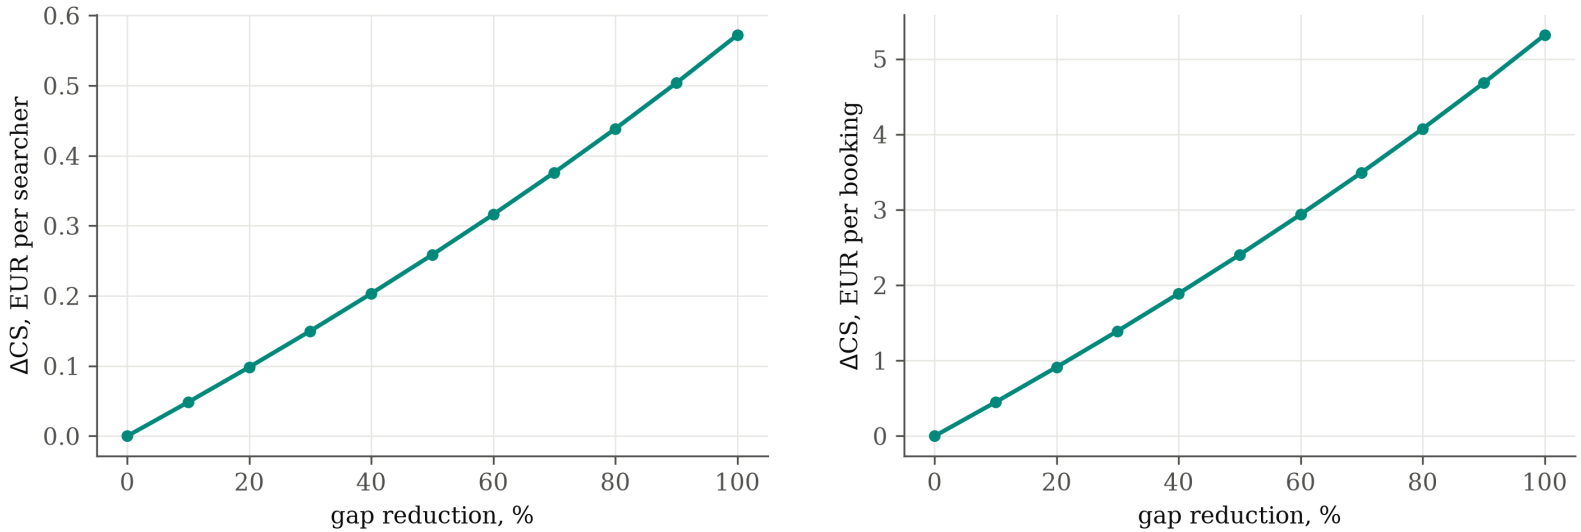

Counterfactual welfare analysis

Counterfactual analysis

- Use the estimated model to value **multimodal technology**: progressively close the searched↔booked gap (observed → full elimination), holding prices and supply fixed (demand-side, partial equilibrium).

  (a) **Consumer surplus** — compensating variation as the gap shrinks, per searcher and per booking.
  (b) **Extensive margin** — how the share of searchers who book rises, and for which mode.
  (c) **Pricing the technology** — a uniform surcharge: how much before the gains vanish.

(a) Closing the gap raises consumer surplus

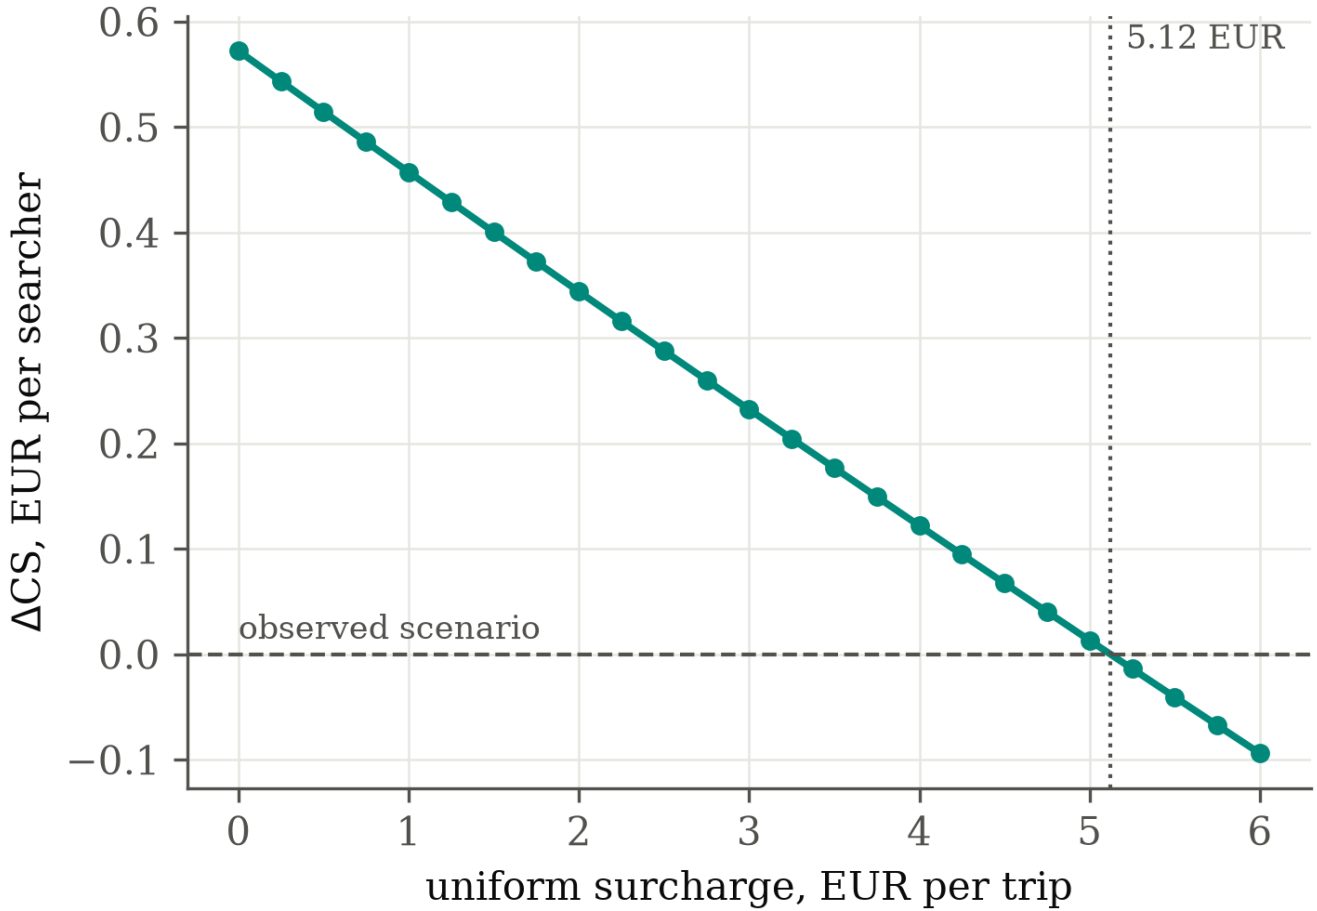

Change in consumer surplus as the gap is reduced (0% = observed). Full elimination: $+0.57$ EUR per searcher (left) and $+5.6$ EUR per booking (right) — ≈10.4M EUR in aggregate, about a quarter of a fare, with no new capacity.

(b) ...and expands the market, mostly through carpool

Share of searchers who book as the gap is reduced. Overall $10.75\% \to 11.6\%$ $(+8\%)$; carpool $5.75\% \to 6.25\%$ vs. bus $5.0\% \to 5.33\%$.

(c) The platform can price it — up to ≈5 EUR per trip

Consumer surplus per searcher under full gap elimination against a uniform surcharge. Break-even at 5.12 EUR per trip (≈ a quarter of a fare, near the current commission); below it the average consumer is better off.

Conclusion

Conclusion

- We study the value of **multimodal technology** on a long-distance platform, using the spatial gap between searched and booked trips.
- Spatial mismatches are common (34% of bookings) and **costly**: consumers would pay 6.95 EUR to close the average gap.
- Eliminating the gap raises welfare and expands the market:
  - +10.4M EUR in consumer surplus, with no new capacity.
  - Booking rate up 8%, mostly through carpooling.
- The platform could **price** the technology (up to ≈5 EUR per trip) and still leave the average consumer better off.

A broader research agenda

- This paper is the **first step**: it documents and prices the consumer cost of searched-vs-booked mismatches, and the demand-side value of integration.
- **Next**: a structural matching model of the two-sided platform (ride requests, bookings, BlaBlaBus) — entry, matching, and platform pricing.
- **Methodology**: a companion paper developing a method to estimate the gap when it is *not directly observed*.
- **Beyond**: the same mismatch lens — optimal vs. chosen option under search frictions — applies to other markets.

Thank you!

Appendix: computing willingness to pay

WTP is the money a consumer trades off against the gap — the marginal rate of substitution between gap and price:

$$\mathrm{WTP}_i = \frac{\gamma}{\alpha_i}\,\Delta G, \qquad \alpha_i = \alpha + \pi^p d_i$$

- γ: gap disutility (second stage, spec. 4); α_i: heterogeneous price sensitivity (both stages).
- Both are negative, so $\gamma/\alpha_i > 0$ — euros a consumer would pay to remove a unit of gap.
- Expressed per 100 km, then evaluated at the average gap $\Delta G = 49.3$ km $\Rightarrow$ 6.95 EUR.
- Heterogeneity enters through α_i: younger, more price-sensitive travelers pay less; privacy-sensitive pay most.
- Confidence bands: parametric bootstrap (10,000 draws).

Back
